Abstract
This paper presents an executable rewriting logic semantics of K-Scheme, a dialect of Scheme based (partially) on the informal definition given in the R’RS report (Kelsey et al. 1998). The presented semantics follows the K language definitional style (Roșu 2005 and 2006) and is a pure rewriting logic specification (Meseguer 1992) containing 772 equations and 1 rewrite rule, so it can also be regarded as an algebraic denotational specification with an initial model semantics. Rewriting logic specifications can be executed on common (context-insensitive) rewrite engines, provided that equations are oriented into rewrite rules, typically from left-to-right. While in theory rewriting logic specifications can let certain behaviors underspecified, thus allowing more models, in practice they need to completely specify all the desired behaviors if one wants to use their associated rewrite systems as “interpreters”, or “implementations”. To become executable, K-Scheme overspecifies certain features left undefined on purpose in R’RS. In spite of overspecifying for executability reasons, the rewriting logic semantics in this paper is the most complete formal definition of a language in the Scheme family that we are aware of, in the sense that it provides definitions for more Scheme language features than any other similar attempts. The presented executable definition of K-Scheme can serve as a platform for experimentation with variants and extensions of Scheme, for example concurrency. The Maude system is used in this paper, but other rewrite engines could have been used as well. Even though, on paper, K rewrite-based definitions tend to be as compact and high-level as reduction-based definitions with evaluation contexts, their complete Maude specification is rather verbose and low-level. An automated translator from K to Maude is under development, which will reduce the size of definitions following the K style several times and will certainly increase their readability. The complete Maude specification is public, together with a web-based interface to “execute” K-Scheme programs without having to download Maude.

1. Introduction
Scheme is a general purpose programming language with a unified handling of data and code. It also has a powerful macro system, using pattern matching, to express syntax transformations. The Revised R’RS Report on the Algorithmic Language Scheme (Kelsey et al. 1998)) gives a thorough, but informal description of the language, as well as a partial denotational semantics. The denotational semantics in (Kelsey et al. 1998) is missing definitions of important language features, such as definitions of eval and dynamic-wind, it does not define the “top level” used throughout the informal specification, and, most importantly, it is not executable. Executability of a language definition gives one confidence in the appropriateness of the definition. Indeed, one can execute hundreds of programs exercising various language features or combinations of features, and thus find and fix errors in the definition. Many subtle errors were detected and fixed in our subsequent definition due to its executability.

Recent attempts have been made at giving formal, operational/executable semantics to fragments of Scheme (Matthews and Findler 2005; d’Amorim and Rosu 2005). Unfortunately, the partial definition in (d’Amorim and Rosu 2005) does not use a proper representation for vectors and lists, so it cannot be extended to the complete Scheme, and neither (Matthews and Findler 2005) nor (d’Amorim and Rosu 2005) gives definitions for quasiquote or macros. Furthermore, neither uses a unified representation of data and code, which is one of the crucial defining aspects of Scheme. These approaches, their limitations and comparisons with our current definition are further discussed in Section 4.

In this paper we introduce a novel formal executable definition of K-Scheme, a dialect of Scheme based (partially) on R’RS. Note that we use the term K-Scheme to interchangeably refer to the definition of K-Scheme, presented here in Maude, and the dialect of Scheme defined by our definition. K-Scheme uses a proper representation for lists and vectors, a unified representation of code and data, and defines quasiquote and a large portion of define-syntax macros. This definition uses the K definitional technique (Roșu 2005 and 2006) within rewriting logic (Meseguer 1992). K is a language definitional framework consisting of the K-technique, based on a first-order representation of computations as lists or stacks of “computational tasks”, and of the K-notation, a domain-specific notation within rewriting logic that ease understanding and defining programming languages. Rewriting logic is a unified logic for concurrency that extends equational logic with transitions; we mostly use the equational fragment of rewriting logic in this paper. One rule is used in order to support unspecified order of evaluation for procedure application forms. One of the driving goals of K-Scheme has been to show the viability of K for defining complex, real world languages, like Scheme. Scheme was chosen particularly for its meta-programming facilities, which provide a strong test for K. We chose to implement this definition directly in Maude (Clavel et al. 2002) using the K-style because,
currently, there is no automatic translator from the K notation to Maude. In K notation the definition would be far more high level. This is no different than the way one would use Haskell, for example, to capture a big-step, small-step, or a context reduction definition. A hasty or semantics reluctant reader may take our executable definition as an “implementation of Scheme in Maude” because it is quite efficiently executable, but in reality the Maude definition of K-Scheme is nothing but an initial model. The resulting perceived “implementation” comes as a bonus. Admittedly some features of R^2RS which are under-specified (e.g., the behavior of eqv?) are specified in this definition, so it is more proper to say that K-Scheme defines a language derived from Scheme in which points of ambiguity, which interfere with executability, have been made unambiguous. Again, we also refer to this derived language as K-Scheme. In the future, however, we intend to address these shortcomings; we do not consider K-Scheme a finished project.

Currently, K-Scheme consists of 772 Maude equations and 1 rule. 192 of them for define-syntax macros and 575 for the core of the language (and a few built-in procedures). We define 60 features of Scheme, using 310 auxiliary operators and 2152 lines of Maude code; 374 lines of code, however, define aspects of the K framework also common to other language definitions, and simple helping operations. Also, we note that many features of Scheme for which we give Maude code definitions could be written as Scheme macros (e.g., procedure definitions), but we did not follow that approach.

The complete Maude definition of K-Scheme can be found on K-Scheme’s webpage at (Meredith et al.), together with a web interface allowing one to “execute” programs directly within K-Scheme’s definition, using Maude’s capability to execute rewriting logic specifications. The main limitations of K-Scheme at this point are an incomplete standard library and the support of only integers among the numeric types. These, as well as other implementation-specific features of Scheme, can be added modularly (i.e., without having to modify the definitions of the existing features) and will be added eventually. Nevertheless, this is the most complete formal definition of a Scheme-like language of which we are aware. In particular we believe we are first to give formal definitions to the operations of quasiquote, unquote, unquote-splicing, and a partial definition of define-syntax.

On Rewriting Logic Semantics and K. This paper is part of the rewriting logic semantics (RLS) project (see (Meseguer and Roşu 2007, 2004) and the references there). The broad goal of the project is to develop a tool-supported computational logic framework for modular programming language design, semantics, formal analysis and implementation, based on rewriting logic (Meseguer 1992). It has been shown in (Şerbânuţă et al. 2007) that conventional definitional styles, such as big-step (Kahn 1987) and small-step SOS (Plotkin 1981), MSOS (Mosses 2004), reduction semantics with evaluation contexts (Wright and Fellesien 1994), the chemical abstract machine (Bouy and Boudol 1992), and continuation-based semantics, can all be faithfully captured, in the sense of intended computational granularity, as rewrite logic theories. Therefore, rewriting logic can be indeed used as an ecumenical framework for language definition using any of the above-mentioned styles, inheriting all their advantages and disadvantages.

K (Roşu 2005 and 2006) is an attempt to optimize the use of rewriting logic for language definitions without obeying any of the styles above; it is, though, closest in spirit to continuation-based semantics, in that it maintains the current computation as a special structure that can be manipulated like any other data-structure, in particular altered. The K technique uses a subset of rewriting logic and can be easily supported by other frameworks, for example by functional programming systems; however, in that case one would use K for the sole purpose of implementing interpreters.

2. Rewriting Logic Semantics

This section provides a brief introduction to term rewriting, rewriting logic, and the use of rewriting logic in defining the semantics of programming languages. Term rewriting is a standard computational model supported by many systems; rewriting logic (Meseguer 1992; Martí-Oliet and Meseguer 2002) organizes term rewriting modulo equations as a complete logic and serves as a foundation for programming language semantics (Meseguer and Roşu 2004, 2006, 2007). Continuation-based rewriting logic semantics, the form of rewriting logic semantics adopted in this paper, provides explicit representations of control context which can be used in the definitions of language features that manipulate this context, such as continuations, exceptions, or jumps.

2.1 Term Rewriting

Term rewriting is a method of computation that works by progressively changing (rewriting) a term. This rewriting process is defined by a number of rules – potentially containing variables – which are each of the form: \( l \rightarrow r \). One step of rewriting is performed by first finding a rule that matches either the entire term or a sub-term. This is done by finding a substitution, \( \theta \), from variables to terms such that the left-hand side of the rule, \( l \), matches part or all of the current term when the variables in \( l \) are replaced according to the substitution. The matched sub-term is then replaced by the result of applying the substitution to the right-hand side of the rule, \( r \). Thus, the part of the current term matching \( \theta(l) \) is replaced by \( \theta(r) \). The rewriting process continues as long as it is possible to find a sub-term, rule, and substitution such that \( \theta(l) \) matches the sub-term. When no matching sub-terms are found, the rewriting process terminates, with the final term being the result of the computation. Rewriting, like other methods of computation, may not terminate.

There exist a plethora of term rewriting engines, including ASF (van den Brand et al. 2002), Elan (Borovansky et al. 1998), Maude (Clavel et al. 2002), OBJ (Goguen et al. 2000), Stratego (Visser 2003), Tom (Kirchner et al. 2005), and others. Rewriting is also a fundamental part of existing languages and theorem provers. Term rewriting is inherently parallel, since non-overlapping parts of a term can be rewritten at the same time, and thus fits well with current trends in architecture and systems.

2.2 Rewriting Logic

Rewriting logic is a computational logic built upon equational logic which provides support for concurrency. In equational logic, a number of sorts (types) and equations are defined. The equations specify which terms are considered to be equal. All equal terms can then be seen as members of the same equivalence class of terms, a concept similar to that from the \( \lambda \) calculus where \( \lambda \) terms can be grouped into equivalence classes based on relations such as \( \alpha \) and \( \beta \) equivalence. Rewriting logic provides rules in addition to equations, used to transition between equivalence classes of terms. This allows for concurrency, where different orders of evaluation could lead to non-equivalent results, such as in the case of data races. The distinction between rules and equations is crucial for formal analysis, since terms which are equal according to equational deduction can all be collapsed into the same analysis state. Rewriting logic is connected to term rewriting in that all the equations and rules of rewriting logic, of the form \( l \rightarrow r \) and \( l =_r r \), respectively, can be transformed into term rewriting rules by orienting them properly (necessary because equations can be used for deduction in either direction), transforming both into \( l \rightarrow r \). This provides a means of taking a definition in rewriting logic and a term and “executing” it.

2.3 Maude: A Rewriting Logic System

In this paper we discuss a rewrite logic definition of K-Scheme using Maude (Clavel et al. 2002), a high-performance rewriting logic
system. In Maude, equations are defined as $\text{eq } l = r$, while rules are defined as $\text{rl } l \Rightarrow r$ (the $\Rightarrow$ symbolizing a one-way transition, versus an equality). Conditions may be added to both equations and rules, with conditional equations represented as $\text{ceq } l = r \text{ if } c$. Terms, such as $l, r$, and $c$ above, are formed from operations, defined using the keyword $\text{op}$, and from variables, declared using the keyword $\text{var}$; by convention, operator names start with lowercase letters or symbols, while variable names start with uppercase letters. Equations and rules can be used directly to execute a program based on a rewriting logic definition.

Maude provides several capabilities beyond standard equations and rules which make it useful for defining languages and performing formal analysis of programs. Maude allows commutative and associative operations with identity elements, allowing straightforward definitions of language features which make heavy use of sets and lists, such as sets of program state information and lists of computational tasks. Maude also provides built-in support (not explored in this paper) for model checking and breadth-first state space exploration, using the rules defined in the semantics to indicate competing tasks (memory accesses, lock acquisition, etc) which can split the state space.

2.4 K: A Computation-based Rewriting Logic Semantics

K (Roşu 2005 and 2006) is a rewriting logic semantics framework consisting of a technique and a specialized notation, to define programming languages as rewriting logic theories. In this paper, we use the K technique to define K-Scheme in Maude; the reader interested in the K notation, as well as in further details regarding the K technique, is referred to (Roşu 2005 and 2006). By K, we understand the K definitional technique within rewriting logic.

In K, the current program is represented as a potentially nested “soup”, (or multi-set), of terms representing the current computation, memory, global definitions, etc. Information stored in the state can be nested, allowing logically related information to be grouped and manipulated as a whole. The most important piece of information is the Computation, wrapped by the operator $k$, which is a first-order representation of the current computation, made up of a list of computational tasks separated by $\rightarrow$. The computation can be seen as a stack, with the current computational task at the left and the remainder (continuation) of the computation to the right. This stack, along with other state components, can be saved and restored later, allowing complex control structures to be defined. For example, if in a certain definitional context where the remaining computation is represented by $k$ one wants to schedule for processing/evaluating expression $E$, all one needs to do is replace the current computation in the state configuration by $E \rightarrow k$. After $E$ evaluates to value $V$ the computation will be $V \rightarrow k$.

Lists, used frequently in K, and Maude definitions in general, are defined in Maude as associative operations with identity elements. An example is ValueList:

sort ValueList .
subsort Value < ValueList .

\begin{align*}
\text{op} \text{nil} & : \rightarrow \text{ValueList} . \\
\text{op} \text{cons} & : \text{ValueList ValueList} \rightarrow \text{ValueList} \\
& \{\text{assoc id: nill}\} .
\end{align*}

Here, ValueList can be seen as a new “type”, or sort; Value is declared to be a subsort, meaning that a Value can be treated as a (trivial, one element) ValueList. nill is declared as an operation with no arguments, also called a constant, of result sort ValueList, and is made the identity of the list formation operation, $\text{cons}$, which allows us to assume that the list always has a tail (since we can always add nill to the end of the list). List formation is associative, allowing us to arbitrarily group elements in the list, but is not commutative, since order is important.

Multisets are defined similarly in Maude, but are also commutative. An example is Env, which represents environments:

\begin{align*}
\text{sort} \space \text{Env} . \\
\text{op} \text{empty} & : \rightarrow \text{Env} . \\
\text{op} \text{assignTo} & : \text{Name Location} \rightarrow \text{Env} . \\
\text{op} \text{assignTo} & : \text{Name Value} \rightarrow \text{Env} \{\text{assoc comm id: empty}\} . \\
\text{op} \text{assignTo} & : \text{Name Location} \rightarrow \text{Env} . \\
\text{op} \text{assignTo} & : \text{Name Value} \rightarrow \text{Env} \{\text{assoc comm id: empty}\} .
\end{align*}

Here, again, a new sort, Env, is defined. An environment is either empty or is a pair of Name and Location. We can also form an environment by putting it next to another environment, forming an environment set using the $\text{cons}$ operation; this operation is associative and commutative, with empty as the identity. The final two operations allow environment lookup ($\text{Lookup}$) and modification ($\text{Assign}$).

The definition of these two operations is shown in the three equations. The first defines lookup: when looking up name $X$, if there is a pair with name $X$ and location $L$ in the environment ($\text{Env}$ is the rest – since environments are sets and are defined as commutative, we can always assume that the pair we are interested in is the first pair in the set), return location $L$. The next two equations define environment modification. In the first, the name $X$ is already in the environment with location $L$, and we want to change this to location $L'$, so we update the existing pair, leaving the rest unchanged. In the second, $X$ was not found in the existing environment, so we just add a new pair with name $X$ and location $L$. The first two equations make use of Maude’s complex matching module equations, in this case modulo associativity and commutativity (of operator $\text{cons}$). Here, and in the rest of the paper, we rely on Maude’s order of equation application, since the final equation would also encompass the case in the second equation. One can easily translate our current definition into a Maude definition that is not dependent on equation ordering, making use of Maude features such as “otherwise” and conditional equations, but we do not do this here since these translations tend to make the equations more complex. Methods of automatically translating definitions using these features into pure rewriting logic specifications that maintain the proper algebraic semantics are available for both otherwise (Clavel et al. 2007) and conditional equations (Şerbănuţă and Roşu 2006).

Using lists and sets (combined with the appropriate state infrastructure, defined in Section 3), we can then define more complex equations such as:

\begin{align*}
\text{eq} \ k((V,VL) \rightarrow \text{assignTo}(X,XL) \rightarrow K) \text{ mem}(\text{Mem}) \\
& \quad \text{eq}(\text{Mem}[X,L] \text{ Env}) \rightarrow V . \\
& \quad \text{eq}(\text{Mem}[X,L] \text{ Env}) \rightarrow V .
\end{align*}

This equation assigns a list of values (computed based on a list of expressions) to a list of names. $V$ represents a value at the head of the list of values, with $VL$ representing the tail. Similarly, $X$ represents a name at the head of the list of names, with $XL$ as the tail, $\text{assignTo}$ is a continuation item, and is used to represent the action of assigning computed values to a list of names. $K$ matches the rest of the computation – i.e., the next computational steps once the assignment is complete. $\text{mem}$ represents the current memory, a mapping of locations to values, while $\text{Env}$ represents an environment, (as shown above) a mapping of names to locations. $L$ represents one of these locations.

The equation works as follows: given a name $X$, look up the location at which $X$ is stored. This leverages matching modulo associativity and commutativity (set or multi-set matching) twice, first to bring in both the continuation and the environment parts of the “soup”, and second to identify the proper name/location pair in the environment. With this location, the term representing the
3. K-Scheme in Rewriting Logic

In our definition K-Scheme we attempted to cover the entirety of core Scheme as defined, informally, in R\(^3\)RS (Kelsey et al. 1998). As mentioned previously we made the decision to specify many of under-specified attributes of Scheme, and thus K-Scheme must be considered a dialect of Scheme. By “core” we mean those syntactic keywords and procedures not marked as library. We also support select library syntax and procedures, and intend to offer a full standard library in the future. Specifically, our K-Scheme currently includes equations for the following Scheme features:

- \(+, -, *, /\) (integer only), append, and, apply, begin, boolean?,

In terms of syntactic keywords, we support quasiquote and the define-syntax form of macros, which we consider part of the core language. The macro support is not complete, but many standard examples can be handled by our definition. We are primarily lacking only those core procedures which operate on different types of numbers, since K-Scheme currently only supports integers. The predicate number? returns \#t for any integer. Conversions between different data types are currently missing, but are easy to define. Characters, while defined, are currently missing comparison operators. Input and output are currently limited to the procedure display.

The complete definition of K-Scheme using the K-technique can be found on K-Scheme’s webpage at (Meredith et al.).

3.1 Syntax

To make Scheme more palatable to Maude, the internal definition of the syntax used by K-Scheme is slightly different from standard Scheme syntax. We provide an external parser at (Meredith et al.) capable of converting normal Scheme code to K-Scheme code, but currently output from programs uses K-Scheme syntax.

Parenthesis are significant to Maude (to resolve precedence conflicts), so we removed them in favor of square brackets. Note that many Scheme interpreters already allow the use of square brackets to denote parentheses. Maude expects strings to be delimited by double quotes, so strings in our syntax are wrapped in curly braces, for example \{“foo”\}. Character constants use the same \#\(v\) syntax as Scheme, save that Maude characters are single character strings, so a character in K-Scheme looks like \#\(<v>\). The short-cut syntax for quote, quasiquote, unquote, and unquote-splicing needed to be changed, because \#\(“\), \#\(\‘\), and \#\(\‘\) are all significant to Maude. We therefore use \$\(“, \$\(\‘\), \$\(\‘\)\), and \$\(\‘\)\) respectively. All variable names need to be quoted. All examples in this paper are given in normal Scheme syntax, but in some places K-Scheme syntax is used to show output. Also, some of the macro equations use the K-Scheme syntax because they are syntax transformations.

\(1\) We must stress that programs can be written in normal Scheme syntax due to our external parser at (Meredith et al.).

3.2 Scheme State Representation

When defining a language using K, one of the important decisions is the structure of the state. By “state”, we here mean all the information about a program execution snapshot, including the program itself; in this sense, it is like a “configuration” in SOS (Plotkin 1981). The rewrite rules require this state structure to determine the context of equation application. The major concerns are that all needed information be available, and that the state is organized in a logical, extensible manner. Our goal is for additions to the state representation to be possible without breaking existing equations in the semantics, when possible, and vice versa.

The state representation for K-Scheme consists of the components: \(k\), the computation; \(mem\), the store; nextLoc, the next free location in the store; env, the local environment; globalEnv, the global environment; synmap, the syntax map for macros (see Section 3.10); output, the output of the program; and program, the stored syntactic representation for the rest of the program not currently in the continuation.

As the heart of computation, \(k\) is the predominate feature in most of the equations. An effort is maintained to match only the front of the computation in equations, both for ease of understanding, and efficiency reasons.

The store, \(mem\), contains all program values bound to variables, or contained in structures bound to variables. It is a mapping from location (given as the constructor loc with a natural number argument, though any sort with a partial ordering and an increment operator could be used in place of natural numbers) to program values. The natural number value of nextLoc is incremented after every allocation, ensuring that previous store values are not lost.

The environments, env and globalEnv, map program variables (symbols) to locations. A distinction between local environment and global environment is necessary in the presence of closures. When a closure is formed, only the local environment is saved in the closure, thus changes to the referent of variables mapped in the global environment will be visible. This necessity is explained further in Section 3.6. The separation of store from the variable binding of the environment allows for an easier representation of the complex structures in Scheme (e.g. lists, vectors).

Every time the built-in function display is called in a program, its argument is converted to a Maude string representation and appended to the value contained in the output state component.

The last component, program, contains the syntactic representation of all expressions in the program. K-Scheme allows for multiple expressions, which are computed in order, as one would expect from a Scheme program given to an interpreter or compiler in a non-interactive mode. The presence of call-with-current-continuation (call/cc) necessitates program. call/cc requires the entire computation be captured at the point of call, and passed to its argument. If the entire program exists in the computation, then the entire program would be passed to the argument of call/cc; this is not the desired behavior for K-Scheme, and can result in unexpected non-termination cases (see Section 3.7).

The following is the equation creating the initial state:

\[
\begin{align*}
\text{eq run(EL)} &= \{ \text{let (stop mem(empty)) } \\
& \quad \text{eq program(EL) globalenv(empty) env(empty)} \\
& \quad \text{synmap (empty) nextLoc(1) output (none) \}.}
\end{align*}
\]

When the run operator is applied to an ExpList EL, it is placed in the program attribute. stop is a signal to the definition to place the next Expression in the program attribute onto the continuation, or, if none exists, to end execution, it is also the identity operator for computations. Recall that the “computational tasks” listed in the computation with the construct “-> ” are processed in order from left to right. We pass empty environments and stores to
eq \( \text{k}(\text{apply}(\text{fbuiltin}(\text{car}), \text{cell}(\text{L1} . \text{L2}))) \rightarrow \text{K} \) \( \text{mem}(\text{Mem}) \)

  \( = (\text{X} \rightarrow \text{nil}) \) \( \text{then } () \) \( \text{else } (\text{arrest}, \text{X}) \) \( \text{fi} \)

---

**Figure 1. List Operations**

eqv, globalenv, and mem, but these will be populated during initial-
ization. synth is also initialized to be empty. This equation showcases well the attributes of K-Scheme’s state. Note that equa-
tions need only refer to values that are significant to their opera-
tion.

### 3.3 Lists

The aspect of Scheme that we consider as the most important to maintain in K-Scheme is the unified representation for both program and data. All functioning programs are lists. To support the semantics of lists, we use a storage model much like that given in the KRS report (Kelsey et al. 1998).

Internally, all lists are represented as cons cells. Cons cells are pairs of locations, which can be thought of as pointers. To form an actual list, the second location, the cdr of the cons cell, points to another cons cell. We chose this representation both because it is the representation suggested by KRS and because it easily supports desires Scheme functionality. An example is the sharing of cdr’s. Two lists may share cdr’s, wherein the update to the cdr of one list is reflected in the cdr of the list sharing that cdr:

\[
\begin{align*}
\text{define x (list 1 2 3 4)} & \\
\text{define y (list 1 2)} & \\
\text{(set-cdr! y (cdr x))} & \\
\text{y} & \rightarrow (1 2 3 4) \\
\text{(set-car! (cdr x) 9)} & \\
\text{x} & \rightarrow (1 3 4) \\
\text{y} & \rightarrow (1 3 4)
\end{align*}
\]

Because we represent cons cells as pairs of locations, the cdr’s of the cons cells representing x and y in the above example point to the same physical cons cell, and any updates will be reflected in both. The Maude syntax for cons cell is:

```
sort ConsCell .
op {_,_} : Location Location -> ConsCell .
```

This structure also allows the built-in Scheme operations on lists to be handled fairly trivially. Finding the car of a list, x, simply amounts to looking up the value pointed to by the first location in the cons cell representing x.

Recall that due to the program state attribute we only exe-
cute one expression in the continuation at a time. These expres-
sions, however, can be arbitrarily complex. Each complete expres-
sion is first converted into this list representation (before execu-
tion). Execution is on list structures consisting of cons cells, except-
ing the creation of simple constants and variables. For example, in

\[
\text{(define x 4) (display x)}
\]

the x and the 4 are not con-
tained in cons cells; they also have no effect on the output (though they are “executed” by K-Scheme).

Figure 1 shows the Maude definitions for the list operations cons, car, cdr, set-car!, set-cdr, and cons. The presence of apply(fbuiltin(X),V1, V2, ... ) or apply(fbuiltin(X),V1 ,V2, ...) denotes the application of a built-in syntactic keyword or built-in function to the values V1, V2, ..., respectively. The con-
structor cell accepts a cons cell as an argument and creates a value, i.e., \( \text{L1} . \text{L2} \), is a cons cell, while cell(\( \text{L1} . \text{L2} \)) is a value. Mem[\( \text{L} \)] “returns” the value L points to in the store Mem.

The equations defining the semantics of the two set functions place symbol(unspecified) on the continuation because this is the return value of the set functions. We decided to have a literal unspecified value in places where KRS declares the result to be unspecified. It is thus possible to have a list of unspecified values which, when printed, looks like (\#<unspecified> ...). What the set equations say, then, is: take the value V, assign it to the location in the cons cell, and return the unspecified value as a result to the rest of the computation (the continuation).

When cons is applied, we use the makeConsCell operator (several other equations in the definition need to create cons cells, so the complexity is factored out). The equations for makeConsCell are given in Figure 1 as well. Note that because we actually assign to locations, the nextLoc attribute described in Section 3.2 is mod-
ified. The operator assignToLoc has been defined to allow for the assignment of multiple values at a time.

The last equations shown in Figure 1 are for list2Values and list2Names. These are for converting between the Scheme style lists, and flat ValueList’s and NameList’s. ValueList’s are necessary for passing to procedures (among other things), while NameList’s are used for the parameter names for user de-
finied functions (see Section 3.6). To understand why we need to convert a Scheme list into a ValueList, consider the situa-
tion we find in a normal application of a procedure in Scheme.

The application is simply a list, where the car is the procedure, and the cdr is the values passed as arguments to the procedure (e.g., (foo 3 4 5)). To actually apply the function it is neces-
sary to pull those values out of the Scheme list. This is the job of list2Values. The if_then_else fi operator is defined in the Maude prelude (by two trivial equations); nil is the identity element for ValueList’s.

The most interesting feature of list2Names is the way in which improper lists are handled. Before the last name in an improper list, we insert the name arrest (inspired by LISP). This signals to the procedure application equations that a variable number of arguments is to be expected (see Section 3.6).

### 3.4 Vectors and Strings

When defining vectors and strings, we again rely on the Scheme storage model. As KRS mentions "A string... denotes as many lo-
cations as there are characters in the string.... A new value may be stored into one of these locations using the string-set! proce-
2The major difference between syntactic keywords and built-in functions in K-Scheme is that all of the values passed to a function are pre-evaluated, while those to a syntactic keyword are not. This is necessary for constructs such as if.
The length of the vector in the vector, and it is computed when the vector is formed, 
does nothing more than "returning" the length value stored in the vector. make-vector allows for the creation 
of vectors of a given length with an optional initial value.

R5RS states that if no initial value is specified then the value of each vector element is unspecified. To handle the unspecified case we again use the literal value symbol(unspecified). The first two make-vector equations handle vectors of length 0. The second two make-vector equations match these two cases: where make-vector is called with an initial value, and where it is not. Each of these cases defers the work to the operator makeVector. The first parameter to makeVector is the initializer value, so for the unspecified case this value will be symbol(unspecified).

The next two parameters denote the current index being created and the length of the vector, respectively. The last three equations define the operation of the operator makeVector. The first is the start case, when makeVector is first encountered: it creates a new vector value (the vector constructor) and maps a location to index 0, simultaneously, it assigns the initializer value to the newly mapped location. The second equation is the termination case: if the index equals the length, the whole vector has been allocated, so we drop the makeVector operator and "return" the newly completed vector value. The last equation handles the inductive step.

### 3.5 Quote, Quasi-Quote, Unquote, and Unquote-splicing

In a language with a unified representation of code and data it is important to have some way to distinguish data. In Scheme this is handled via quote and its cousin quasiquote. In K-Scheme, evaluation of any list is performed by appending the operator evalk after that list in the continuation (See Section 3.9). The equation for quote is straightforward:

\[
eq k(apply(mbuiltin(quote), V) \rightarrow K) = k(V \rightarrow K)
\]

As can be seen, application of the syntactic keyword quote results in moving its argument onto the top of the continuation. Because it is not succeeded by the operator evalk (unless the rest of the computation matched by the variable K deliberately contains evalk), the list is not evaluated. R5RS allows for an implementation to use the same memory for all references to a quoted expression, so we chose not to copy memory in K-Scheme. This specification that memory is not copied (K-Scheme) rather than need not be copied (R5RS Scheme) is another deviation in K-Scheme from normal Scheme.

#### 3.5.1 Application of Quasiquote, Unquote, and Unquote-splicing

The equations for quasiquote, unquote and unquote-splicing can be seen in Figure 3. Note that in K-Scheme all quasiquote'd expressions are copied, even when they contain no unquote forms. To do otherwise would be extraordinarily complicated, requiring a pass to check for unquote forms. This is another deviation from R5RS Scheme, which does not specify what should happen in the case of quasiquote forms with no unquote terms. Recall that in Scheme quasiquote has the shortcut syntax of `'..`, unquote of `..`, and unquote-splicing of `:'`. The operator qq is placed after that list in the continuation (See Section 3.9). The equation for quasiquote is straightforward:

\[
eq k(apply(mbuiltin(quote), V) \rightarrow K) = k(V \rightarrow K)
\]
The presence of unquote applied to a value during evaluation (the second equation in Figure 3), means that said value must be evaluated before being placed into the list (or vector). Thus the value matched by the variable $V$ is placed on the computation followed by evalex. Also, we unbind unquote and unquote-splicing in order to produce the observed behavior of references to unbound variables. What this means is that a program such as $(\text{list}, 2)$ will result in $(3)$ while $(\text{list}, 3)$ will result in an unbound variable (unquote) error. Again we use the kenv operator to restore the environment after the evaluation of $V$, in this case re-binding unquote and unquote-splicing.

unquote-splicing is very similar to unquote. The difference is that after the evalex we place the operator uqs. This operator will be matched by later equations in order to know that the value preceding it should be spliced into the list (or vector).

#### 3.5.2 Definition of Operator $qq$

The equations in Figure 4 define the operator $qq$. As mentioned in RRS, “Quasiquote forms may be nested. Substitutions are made only for quasiquote components appearing at the same nesting level as the outermost back-quote.” In order to achieve this, $qq$ keeps track of the current nesting depth as a natural number (the flat in the $qq$ operator declaration). unquote is only evaluated when the nesting level of operator $qq$ is 0. The equations for unquote-splicing are essentially identical to those for unquote, so we do not list them. The equations for unquote-splicing are very similar to the equations for make-vector in Section 3.4, the only difference being that the equations essentially copy an already existing vector, and that $qq$ is applied to each of the values in the vector being copied. The only particular caveat is that splicing a list into a vector requires inserting each list element into the vector.

We have an equation for all non-list and non-vector values, so that the addition of a new value type to the definition will not require a modification to the equations for $qq$.

The first equation in Figure 4 corresponds to a quasiquote expression within a quasiquote expression (a nested quasiquote). Because this occurs while copying a list, rather than evaluating a list, we must check to see if the car of the list is the symbol quasiquote, rather than the equations seen previously where we matched the apply operator with a specific built-in function or syntactic keyword. This same strategy of looking at the car of the cons cell is used in all of the $qq$ equations where the argument to $qq$ is a cons cell. If the car of a cons cell is symbol quasiquote we create a new cons cell consisting of the symbol quasiquote and $qq$ applied to the cdr of the cell (as the cdr very well could be an

```
Figure 3. Quasiquote, Unquote, and Unquote-splicing

The presence of unquote applied to a value during evaluation (the second equation in Figure 3), means that said value must be evaluated before being placed into the list (or vector). Thus the value matched by the variable $V$ is placed on the computation followed by evalex. Also, we unbind unquote and unquote-splicing in order to produce the observed behavior of references to unbound variables. What this means is that a program such as $(\text{list}, 2)$ will result in $(3)$ while $(\text{list}, 3)$ will result in an unbound variable (unquote) error. Again we use the kenv operator to restore the environment after the evaluation of $V$, in this case re-binding unquote and unquote-splicing.

unquote-splicing is very similar to unquote. The difference is that after the evalex we place the operator uqs. This operator will be matched by later equations in order to know that the value preceding it should be spliced into the list (or vector).

```

```

```

#### 3.5.3 Unquote-splicing Specifics

Figure 5 shows equations for unquote-splicing. In Scheme, unquote-splicing works much like unquote. It evaluates its argument. However, with unquote-splicing, the argument must evaluate to a list. This list is then *spliced* into its enclosing structure. In simple terms, parentheses are removed. For example $(\text{list}, 3 \text{\textit{\footnotesize 4}})$ results in the list $(1 \text{\textit{\footnotesize 2}} 3 \text{\textit{\footnotesize 4}} 5)$. As noted before, a given value has resulted from the evaluation of an unquote-splicing if it is succeeded by the operator $uqs$.

The first equation in Figure 5 simply reorders the continuation so that evaluation can happen. At this point we have a cons cell at the top of the continuation resulting from the application of unquote-splicing. We know that it must be a cons cell, because the result of an unquote-splicing form must be a list. The re-ordering takes the $qq$ operator after the $uqs$ and places it at the top of the continuation. The cell in front of $uqs$ is placed as the argument of a second $uqs$ operator. Both of these operators were defined in Figure 3. The second equation matches the latter $uqs$ operator, which takes a value as an argument (and this value must be a cons cell). The presence of $uqs$ ($V1$) followed by makePair ($V2$) (another makePair operator defined in our infrastructure), denotes that a cons cell should be made from $uqs$ ($V1$) and $V2$. $uqs$ signals unquote form, or another quasiquote). The makePair operator is a wrapper for makeConsCell, which we saw earlier. The difference is it evaluates and collects its arguments before reducing to makeConsCell. We also increment the nesting depth, ensuring that only the proper number of unquote expressions will be evaluated.

The equations for $qq$ applied to a cons cell in which the car of the cell is unquote are next. If the current nesting depth is 0, the cell is simply evaluated. This will result in eventually matching the equations we saw earlier in Figure 3. If, however, the nesting depth is not 0, the nesting depth is decremented, and we repeat the process of quasiquote repeated within a quasiquote expression. That is, we make a cons cell of the symbol in question (either unquote or unquote-splicing) and $qq$ applied to the cdr of the cons cell. The last case for cons cells happens when the car of the cons cell is none of the three symbols we care about (unquote, unquote-splicing, quasiquote). In this case $qq$ is applied to both the car and cdr or the list, and the resulting values are made into a new cons cell via the makePair operator.

Finally, if the base case where the value in question is not a cons cell (or vector). In this case the value is simply copied into the list (or vector), by placing the value, as-is, onto the top of the continuation. This is correct because any application of a function can only occur within a cons cell.

```

```

```

```

```
3.6 Lambda

The heart of the support for the lambda syntactic keyword is the `fclosure` value type. The operator declaration for `fclosure` can be seen in Figure 6, as well as the equations for `fclosure` application and creation. The `fclosure` operator accepts a `NameList`, a `ValueList`, and an `Env` (environment) as arguments. The `NameList` is a list specifying the name of parameters; recall that we showed how a Scheme-style list is converted to a `NameList` in Section 3.3. The `ValueList` is the body of the procedure. Each Value in the `ValueList` is an expression, so it will either be a cons cell or a simple type such as a variable or an integer. We allow a `ValueList` because the bodies of procedures are allowed to consist of multiple expressions that are to be executed in order, much as expressions given to a `begin` syntactic keyword expression.

The first equation in Figure 6 is for the creation of `fclosure`. Value's via the application of the syntactic keyword `lambda`. The equation says when lambda is applied to a Value V followed by a `ValueList` VL, convert V into a `NameList`, put VL into the `fclosure` as the body, and store Env as the environment of the closure. The reason this works is the syntax of lambda. In a program lambda always has the form `(lambda (names ...)) body`. Because of this we can be sure that the first Value passed to lambda must be a Scheme list consisting of the parameter names. Note that we store only the local environment to the closure, as we stated in Section 3.2. For an example of why we do this consider:

```
(define f #f)
(let ((y 3))
  (set! f (lambda () (+ x y)))
)
```

The idea illustrated here is that x is not referenced until the function is called. When a variable reference is evaluated the local environment is checked first, the global is only checked if there is no reference to the variable in the local environment. Because x exists in the global environment by the time of the second call, there is no unbound variable error. We can see that the local environment must be captured so that y maintains the correct value of 3 after the end of the let scoping.

The next two equations show the application of `fclosure`s. The first thing to notice is that the environment is set to be that of the one stored in the closure, giving us the desired behavior from the above example. In both cases the values passed to the `fclosure` are bound to the names in the `fclosure`'s name list.

In the second equation we see our special symbol `&rest`. Recall that this symbol is inserted by `names2List` when the specified list is improper, because an improper parameter list is Scheme's way of specifying a variable number of parameters to a procedure. When `&rest` appears in the `NameList` we first convert all the Values passed after the `&rest` symbol into a Scheme list and then bind it to the name appearing after the symbol `&rest`. The operator `begin` is a simple operation on `ValueList`s that takes the last Value's of a `ValueList` from a passed number and returns them as a `ValueList`. In this case we pass the length of the `NameList` XL. We then use the `firstN` operator to pull the first Value's out of the list, and bind these to the beginning of the `NameList`. In the third equation the situation is much less complicated, the passed Value's are simply bound to the `NameList`. In both equations we apply the syntactic keyword `begin` to the `ValueList` that is the body of the `fclosure`. Using this strategy, all sequences of expressions `not` at the top level (i.e., within an expression), are handled by the `begin` operator. Because of this, in K-Scheme, any procedure or keyword which requires sequential evaluation (e.g., `do`, `let`, `let*`, `letrec`, etc) apply the keyword `begin` in their equation. The last requirement is to restore the environment after executing the body; this is, again, handled by `kenv`.

`begin` itself is relatively simple. All it does is execute each expression in order and discard the result, except for the last expression where the result is placed on the continuation in order to "return" it. `begin` is defined by the final three equations shown in Figure 6. The first of them is the termination case wherein the `ValueList` being evaluated is exhausted. The last of them, which will only be applied if the termination case cannot be, converts the

operator continue into an evkvalk followed by discard. Operator continue takes no arguments and is just a convenient marker. Discard simply throws away whatever Value precedes it. Recall that evalk is an operator telling the definition to evaluate the Value before it, rather than keeping it as is (see Section 3.9).

3.7 Call-with-current-continuation

In the example, if the continuation of the whole program is grabbed, rather than just the continuation of (call/cc (lambda (c) (set! k c) 4)), this program will not terminate. The reason for this is that (k 3) will be included in the continuation it is calling! This non-termination can be recreated in K-Scheme, or any Scheme implementation, by passing the call/cc expression and (k 3) to begin. Note that this is another case where we chose one possible interpretation of R RS. We persist that grabbing the entire rest of the program would not be desirable, however.

Application of a continuation, as seen in the second equation, simply replaces the current continuation (R2) with the one contained in the continuation operator. The current environment is also replaced by that of the continuation. Note that, unlike fclosure application, the existing environment is not saved by continuation application, v, the value the continuation is applied to, is passed to the remainder of the computation.

K-Scheme also contains definitions for call-with-values and dynamic-wind. While (Matthews and Findler 2005) claims that special consideration for dynamic-wind must be made, we use the version presented in (Dybvig 2003). Instead of actually modifying the objects created by call/cc, this implementation is written completely in Scheme. It does redefine call/cc, but we believe, because it can be written with normal call/cc, that actually modifying the structure of continuation objects is unnecessary.

3.8 Equivalency Predicates

The eqn? function in Scheme is a fairly interesting case. This is one of the features of Scheme for which we currently chose one of the correct interpretations of R RS. Future versions of K-Scheme should have the option of informing the user when the result of eqn? is unspecified in R RS. According to R RS “The eqn? procedure defines a useful equivalence relation on objects. Briefly, it returns #t if obj1 and obj2 should normally be regarded as the same object.” For the most part this is fairly straightforward: two numbers are eqn? if they are equal. The same is true for all simple data types. It is more interesting with complex objects.

Interestingly enough, because of the way we defined our Value types, this comes out to simple equality of terms of sort Value. The = operator in K-Scheme (and in all other rewrite engines) performs a (recursive) comparison of its two term (normal form) arguments, modulo corresponding attributes such as assoc. and comm. If all the sub-objects are equivalent the objects are equivalent. This is similar to equal? in Scheme (explained below). The equation for eqn? is in Figure 8. All it does is return symbol(#t) if the two Value's are equal. This works, because for two cons cells to be equal as Maude terms, they must define the same locations. This holds for strings and vectors as well. It also holds for fclosure's with some interesting results. R RS states that two procedures, when compared via eqn? must return #t if they represent two procedures with different semantics. It says the results of comparing two equivalent procedures is undefined, however. In K-Scheme procedures with different semantics will not be equivalent in terms of Maude equivalency because they will contain different cons cells as the body. There are a few cases where our eqn? will return #t for procedures. Either they can be the same physical procedure (i.e., two procedures bound to a variable x following by (eqn? x x)), or they can be two procedures with the exact same parameters (and parameter names) with the same simple type as the body, e.g.:

```
(eqf? (lambda (x) x) (lambda (x) x)) ===> #t
(eqf? (lambda (y z) 3) (lambda (y z) 3)) ===> #t
(eqf? (lambda (x) y) (lambda (y) y)) ===> #f
(eqf? (lambda (x) '(x)) (lambda (x) '(x))) ===> #f
```

The reason the last example returns #f is because '(x) is not a simple type, and in each lambda expression a different list consisting of only the symbol x is allocated.

Aside from behavior on empty strings and empty vectors, eq? is only allowed to return #t when eqn? returns #t. The idea, as is mentioned in R RS, is that eq can often be more easily implemented (and thus faster) than eqn?, such as with a pointer comparison. Our decision was to use the same implementation for eq? and eqn?, which conforms to the information specification.

equal? is a library procedure that actually recursively compares the elements to complex structures, calling eqn? on simpler
sub-elements (such as numbers). As can be seen in the third equation in Figure 8, when equal? is applied to two Value's we pass these Value's to the operator equal. If equal returns the Maude boolean true, we return the symbol #t, if it returns false, we return #f. The equal operator recursively compares complex structures. In the case of cons cells, two cons cells are equivalent if the car's and cdr's are equivalent (equation four). Vectors are equivalent if all elements they point to are pairwise equivalent (equation five). It is identical for strings, as strings are little more than specialized Value's. Two simple Value's are equivalent if they are equal according to Maude. Since this is what we did for eqv? this is the same as applying eqv? for the simple Value's; exactly what R^{RS} states.

3.9 Eval

We have explained the role of the evalk continuation item operator in previous sections. This is the motor behind the formal definition for the eval procedure. The equation for eval can be seen in Figure 9 (the first equation), as well as the equations for evaluating the different Value types of K-Scheme.

We can see in the first equation that the application of the procedure evalk to a Value V places V on the top of the continuation followed by evalk. evalk also expects an environment Value to be passed. Much like an fclosure, the environment is swapped for the passed environment and restored via kenv after execution.

The second and third equations show the evaluation of symbols. The symbol is looked up in the environment, and the proper location referenced in the store. Note, as was mentioned earlier, the local environment is checked first; the global is only consulted if the local has no binding for the given variable.

The fourth equation handles evaluation of a cons cell. As Scheme requires, the evaluation of a cons cell is always considered to be a procedure or syntactic keyword application (note that user defined macros are expanded before evaluation). The last equation in Figure 9 shows the evaluation of int's. All simple Value types have similar equations, where they are simply placed onto the continuation as-is. Logically this makes sense, as, in Scheme, #4 is the same thing as 4. In the latter, 4 is evaluated, but 4 evaluates to 4!

The operator preApply (Figure 10) decides how to handle the ValueList passed to it. If the first value is a literal mbuiltin (a syntactic keyword) then it is immediately applied, as we do not wish to evaluate the arguments to a syntactic keyword. This equation works because syntactic keywords cannot be bound to variables, so there is no need to worry about a symbol possibly pointing to an mbuiltin. If the first Value is not an mbuiltin this must be the application of a procedure or continuation. If this is the case, all the sub-terms in the application form must be evaluated in an unspecified order. We use a rule (the line marked rl rather than eq) to reflect that there is no specified order of evaluation. This is superior to the R^{RS} denotational semantics, which permutes evaluation, because the order is truly random. This is similar to how the definition of (Matthews and Findler 2005) works, but using rewriting logic rather than reduction semantics with contexts. unEvalWrap wraps all the Value's in a ValueList with the unEval constructor. This tells the rule that such a value has not been evaluated yet. The Value hole is a place holder so that an evaluated value can be placed back in the proper order. randomEval also has a natural number parameter, which tells randomEval what are the all the values that have been evaluated (when it reaches 0 randomEval is replaced by apply as the procedure or continuation application can proceed). The last equation reinserts the evaluated Value where the hole is, to, again, insure that the Value's will be in the proper order. This usage of a rule gives us the proper behavior. A Maude search (Maude searches for all possible solutions) on the following example:

(define y 0)
(define x 0)
(display (begin (set! x 3) y)
(display (begin (set! y 2) x)
(display (begin (set! x 3) y)
)

results in 2, 3, 4, and 7 as possible answers.

3.10 Macros

K-Scheme supports the use of top-level define-syntax to define new macros. This support is under development, so the types of macros that can be defined are still limited: most macros with list-based patterns can be defined, but patterns with improper lists or vectors are still not supported. Macros are also assumed to not define new names using internal defines or reference free-names not defined at top-level. Even with these limitations, K-Scheme can support a number of standard macros, such as those used to define constructs like or and let. This provides two definitions of these constructs, one via semantic rules and one based on translation into more basic constructs. Currently, macros are not hygienic or referentially transparent. Macro expansion happens up front, taking a K-Scheme expression with macros and yielding an expression
3.10.1 Processing Macro Definitions

When a macro definition is encountered, K-Scheme processes each provided pattern, transforming it into a form which can more easily be used during matching. These patterns, along with the associated templates, are then stored in a syntax definition map keyed by name. This allows definitions to be quickly found during macro expansion.

\[
\text{op trans} : \text{List NameList} \rightarrow \text{List}.
\]
\[
\text{ceq trans} (\ [ X , I , IL \] , \ [ IL' \] , NL )
= \text{trans} (\ [ I , IL \] , \ [ IL' \] \ \text{patVar}(X,0) \] , NL )
\]
\[
\text{if} \ \text{nameIn}(X,NL) = \text{false} \ \text{and} \ \text{isEllipses}(I) = \text{false}.
\]

The initial pattern is transformed using the \text{trans} operator, the definition of which is shown above. \text{trans} takes the original list, a working list (the post-transformation list), and a list of names. The names are the literals defined in \text{syntax-rules}, and are used to distinguish literals from pattern variables. The sample equation shows a potential match. Here, a name, \text{X}, is at the head of the list being processed. If it is not in the list of literal names, checked with \text{nameIn}, and if the following list item is not an ellipses, checked with \text{isEllipses}, then \text{X} is a non-repeating pattern variable, and is marked as such in the working list. The item that represents non-repeating pattern variables, \text{patVar}, includes the name of the variable and a counter, which represents the ellipses “depth” of the variable; this allows us to detect when the ellipses count between the pattern and the template do not match.

3.10.2 Macro Expansion

To support macro expansion, all expressions processed by K-Scheme are first checked to determine if they make use of any defined macros. If a macro usage is found, the macro is expanded, replacing it with the generated syntax. The expression is then checked again, with this process repeated until no further expansions occur. This model naturally supports both recursive patterns and the use of multiple distinct macros in an expression. The operators that control this process are shown below:

\[
\text{op applySyntax} : \text{ExpList symmap} \rightarrow \text{ExpList}.
\]
\[
\text{op applyToExp} : \text{Exp symmap} \rightarrow \text{Exp}.
\]
\[
\text{op applyOneStep} : \text{Exp symmap} \rightarrow \text{Exp}.
\]

The first operator, \text{applySyntax}, is invoked each time a new list of expressions is processed by K-Scheme. It makes use of \text{applyToExp} to apply the syntax in the syntax map (\text{symmap}) to each expression. \text{applyToExp} applies one step of syntax transformation using \text{applyOneStep}, repeating this process until the expression no longer changes.

\[
\text{ceq applyToExp}(E,SM) = \text{applyToExp}(E',SM)
\]
\[
\text{if} \ E' := \text{applyOneStep}(E,SM) \ \text{and} \ E =/\ E'.
\]
\[
\text{eq applyToExp}(E,SM) = E.
\]

The first equation shows the case where the expression does change, meaning that \text{E} contained a use of a macro that was then expanded in \text{E}'. In this case, we continue looking for macros to expand in \text{E}'. The second equation represents where no changes were found (i.e., where the first equation did not apply). In this case, the expression \text{E}, now fully expanded, is returned.

3.10.3 Matching and Substitution

Expansion works using a two step process. In the first step, matching, the expander searches for a pattern that matches the supplied syntax. The list of patterns associated with the macro keyword is tried in order. If a match is found, a mapping from pattern variables to expression syntax is returned. Alternatively, match failure causes the next pattern to be tried in turn. The \text{match} operation, with a sample equation, is shown below:

\[
\text{op match} : \text{List List MatchPairs} \rightarrow \text{MatchPairsXBool}.
\]
\[
\text{eq match}(\ [ E , IL \] , \ [ patVar(X,N) , IL' \] , MPs )
= \text{match}(\ [ IL , IL' \] , MPs \ \text{patVar}(X,N), E )).
\]

Here, \text{match} takes two lists. The first contains the current syntax being processed, while the second contains the pattern. The final parameter is a set of pairs, where each pair is a map of pattern variables to the syntax they are matched to. The final result is this set along with a flag indicating whether matching was successful. The equation shows a sample match. The next term in the pattern to match is a pattern variable, \text{X}, if the next term in the syntax list is an expression, \text{E}, the match of \text{X} to \text{E} is recorded in the set of matches.

The second expansion step is substitution. Substitution uses the mapping found during matching, along with the template associated with the matched pattern, to expand the macro to the proper syntax. Variables in the pattern are replaced with the expression syntax from the mapping, taking proper account of ellipses.

The \text{subst} operation, with a sample equation, is shown below:

\[
\text{op subst} : \text{Exp Exp List} \rightarrow \text{Exp}.
\]
\[
\text{ceq subst}(\ [ X , I , IL \] , \ [ IL' \] , M, Mps)
= \text{subst}(\ [ I , IL \] , \ [ IL' \] , M, Mps)
\]
\[
\text{if} \ \text{isEllipses}(I) = \text{false}.
\]

The \text{subst} operator takes a template expression, the first argument, and generates the expanded expression, built up in the second argument and eventually returned. The third parameter is a natural number, used to track expansion properly for repeating names and repeating lists. The final parameter is the set of matches developed using the \text{match} operation. The equation shows an example of substituting the value matched to a pattern variable in the match operation for a pattern variable in the template. Here, if name \text{X} is encountered, and is not followed by ellipses, and if \text{X} is also the name of a pattern variable matched to list item \text{I}', \text{X} is removed from the template list and \text{I}' is added to the end of the working list. When \text{subst} has emptied the template list, it is finished, and will return the working list.

3.10.4 Example: Or

A standard example of \text{define-syntax} is the definition of \text{or}:

\[
\text{(define-syntax or}
\text{(syntax-rules ()
((\_ \#f))
((\_ e) e)
((\_ e1 e2 e3 ...) \text{let} ((t \text{e1}) (if t t (or e2 e3 ...))))))
\]

This pattern includes multiple cases and the use of recursion (in the last case). Expansion works as expected: (\text{display } (\text{or})) translates to [\text{display } \#f], while (\text{display } (\text{or } (\> 1 2) (\> 3 4))) translates to [\text{display } (\text{let} [(t \> 1 2)] (if t t \text{'} [t \text{'} \text{'} 3 4]))].

3.10.5 Example: Let

Another standard example is the definition of \text{let}, given as:

\[
\text{(define-syntax let}
\text{(syntax-rules ()
((\_ (X E) ...) B ...)
((\_ \text{lambda} (X ... ) B ...) E ...)))
\]

This pattern includes just one non-recursive case, but the use of repeating pattern variables is more complex than in the case of or. Again, expansion works as expected: (\text{let } (\text{a 5} (b 6)) (\text{display } (+ a b)) (\text{display } (+ a b))) expands to [\text{[lambda} ['a 'b] [\text{display } ['+' 'a 'b']] [\text{display } ['* 'a 'b]] 5 6)].
3.10.6 Example: Nested Ellipses

A third example illustrates the use of nested ellipses:

\[(\text{define-syntax test})\]
\[(\text{syntax-rules () ((\_ (X ... ...) ...) (\list X ... ...)))})\]

This pattern "strips off" the surrounding list structure, combining all items into a single list. For instance, \[(\text{display (test (1 2 3 4) (5 6) (7) (8 9 10)))}\] expands to \[(\text{display [1 2 3 4 5 6 7 8 9 10])}\].

4. Comparisons and Related Work

The K technique has been used to define several languages previously. Kool (Hills and Rosu 2007b,a) is an object-oriented language designed to show how object-oriented language features can be defined in the K framework. A formal definition of Java (Farzan et al. 2004) given in an earlier rewriting logic semantics style from which K descended also exists. There is also a pre-alpha definition of Prolog using K at (Serbănuţă et al.). Again, one of our main goals of this project has been to show K's definitional viability by defining a language with heavy meta-programming capabilities.

Previous attempts at defining Scheme, or portions of Scheme, also exist. As already mentioned (Kelsey et al. 1998) gives a partial denotational semantics of Scheme which misses several features (\text{dynamic-wind}, \text{eval}, a "top level", etc.), and is not executable.

\[\text{(d'Amorim and Rosu 2005) attempts a rewriting based approach to an operational semantics for Scheme. Our work inherits nothing from this. (d'Amorim and Rosu 2005) does not use a list-like internal representation, most operations being performed directly on the program syntax. In order to support \text{quote} and \text{eval}, which is mistakenly called \text{unquote} (referred to as \text{eval} in the following), quotes creates a "frozen" expression, which can be later evaluated by \text{eval}. This is an incorrect approach because it means that only expressions generated by \text{quote} can be evaluated by \text{eval}. Our approach is general and supports the evaluation of arbitrary lists, as it should. We also feel that our evaluation of an internal list representation is more in the spirit of the language. Another problem with (d'Amorim and Rosu 2005) is that lists themselves are represented as \text{ValueList}'s rather than cons cells. This would not allow for sharing of cdr's between lists. This works for the subset defined because list modification was not supported (no set-car! or set-cdr!). Vectors are also mishandled as \text{ValueList}'s, when they should be lists of locations. eqv? could not be handled properly within this framework either. \text{quasiquote} was also not supported (and adding support for it would be difficult, due to the lack of proper list representation).

\[\text{(Matthews and Findler 2005) provided an operational semantics of RRS Scheme. The main contributions of their paper were a greater completeness than the formal definition given in RRS (they added \text{eval}, \text{quote}, and \text{dynamic-wind}, modeling multiple return values in a way that is transparent to the rest of the definition, a model of undefined order of evaluation, and that the executability of their definition. We provide a definition of a dialect of Scheme with more features, offering \text{define-syntax}, \text{quasiquote}, \text{unquote}, and \text{unquote-splicing}. Our \text{eval}, unlike the definition in (Matthews and Findler 2005), also supports the environment parameter mentioned in RRS. Multiple return values (only appropriate within the context of \text{call-with-values}) are transparently handled in our definition, \text{vala} being a particular \text{Value} type. As mentioned earlier, we do not feel modification of continuations is necessary to support \text{dynamic-wind}, because an implementation completely written in Scheme exists in (Dybvig 2003). We also feel our definition is more true to the spirit of Scheme with regards to how code and data have a unified representation, rather than only using a list structure in the presence of \text{quote}, \text{cons}, \text{list}, etc. (as in (Matthews and Findler 2005)). This last is a subjective assessment, however.}

5. Future Work and Conclusions

Eventually, we intend to provide complete support for macros, with \text{let-syntax} and \text{letrec-syntax}, as well as support for macros involving improper lists and vectors. This will also entail hygiene and referential transparency. Furthermore, we intend to provide full support for the entire Scheme standard library (excepting input, due to the nature of the Maude).

We have presented a formal definition K-Scheme, a dialect of Scheme very similar to RRS Scheme, using the K definitional style within rewriting logic. The complete source and an online trial of our definition can be found at (Meredith et al.). Unlike earlier formal, executable definitions, we provide definitions for quasiquote, unquote, unquote-splicing, and \text{define-syntax} (with portions of its associated pattern language).
